# Range functions of any convergence order and their amortized complexity analysis 

Kai Hormann • Chee Yap • Ya Shi Zhang

#### Abstract

We address the fundamental problem of computing range functions $\square f$ for a real function $f: \mathbb{R} \rightarrow \mathbb{R}$. In our previous work [9], we introduced recursive interpolation range functions based on the Cornelius-Lohner (CL) framework of decomposing $f$ as $f=g+R$, which requires to compute $g(I)$ "exactly" for an interval $I$. There are two problems: this approach limits the order of convergence to 6 in practice, and exact computation is impossible to achieve in standard implementation models. We generalize the CL framework by allowing $g(I)$ to be approximated by strong range functions $\square g(I ; \varepsilon)$, where $\varepsilon>0$ is a user-specified bound on the error. This new framework allows, for the first time, the design of interval forms for $f$ with any desired order of convergence. To achieve our strong range functions, we generalize Neumaier's theory of constructing range functions from expressions over a Lipschitz class $\Omega$ of primitive functions. We show that the class $\Omega$ is very extensive and includes all common hypergeometric functions. Traditional complexity analysis of range functions is based on individual evaluation on an interval. Such analysis cannot differentiate between our novel recursive range functions and classical Taylor-type range functions. Empirically, our recursive functions are superior in the "holistic" context of the root isolation algorithm EVAL. We now formalize this holistic approach by defining the amortized complexity of range functions over a subdivision tree. Our theoretical model agrees remarkably well with the empirical results. Among our previous novel range functions, we identified a Lagrange-type range function $\square_{3}^{L^{\prime}} f$ as the overall winner. In this paper, we introduce a Hermite-type range function $\square_{4}^{H} f$ that is even better. We further explore speeding up applications by choosing non-maximal recursion levels.

## 1 Introduction

Given a real function $f: \mathbb{R} \rightarrow \mathbb{R}$, the problem of tightly enclosing its range $f(I)=\{f(x): x \in I\}$ on any interval $I$ is a central problem of interval and certified computations [11,13]. The interval form of $f$ may be ${ }^{1}$ denoted $\square f: \square \mathbb{R} \rightarrow \square \mathbb{R}$, where $\square \mathbb{R}$ is the set of compact intervals and $\square f(I)$ contains the range $f(I)$. Cornelius and Lohner [3] provided a general framework for constructing such $\square f$. First, choose a suitable $g: \mathbb{R} \rightarrow \mathbb{R}$, such that for any interval $I \in \square \mathbb{R}$, we can compute $g(I)$ exactly. Then, $f(I)=g(I)+R_{g}(I)$, where $R_{g}(x):=f(x)-g(x)$ is the remainder function. The standard measure for the accuracy of approximate functions like $\square f$ is their order of convergence $n \geq 1$ on $I_{0} \in \square \mathbb{R}$, that is, there exists a constant $C_{0}>0$, such that $d_{H}(f(I), \square f(I)) \leq C_{0} w(I)^{n}$ for all $I \subseteq I_{0}$, where $d_{H}$ is the Hausdorff distance on intervals and $w(I):=b-a$ is the width of $I=[a, b]$. Suppose $R_{g}$ has an interval form $\square R_{g}$ with convergence order $n \geq 1$. Then,

$$
\begin{equation*}
\square_{g} f(I):=g(I)+\square R_{g}(I) \tag{1}
\end{equation*}
$$

is an interval form for $f$ with order of convergence $n$. This is an immediate consequence of the following theorem.

Theorem A [3, Theorem 4]. The width of the remainder part satisfies

$$
d_{H}\left(f(I), \square_{g} f(I)\right) \leq w\left(\square R_{g}(I)\right) .
$$

Prior to [3], interval forms with convergence order larger than 2 were unknown. Cornelius and Lohner showed that there exists $g$ such that $\square R_{g}$ has convergence order up to 6 in practice and up to any $n \geq 1$ in theory.

[^0]Example 1. Let $g(x)$ be the Taylor expansion of $f(x)$ at $x=m$ up to order $n \geq 1$ and $R_{g}(x)=\frac{f^{(n+1)}\left(\xi_{x}\right)}{(n+1)!}(x-m)^{n+1}$ for some $\xi_{x}$ between $x$ and $m$. Then,

$$
\begin{equation*}
\square R_{g}(I):=\frac{\left|\square f^{(n+1)}(I)\right|}{(n+1)!}(I-m)^{n+1} \tag{2}
\end{equation*}
$$

is a range function for $R_{g}(I)$, where $I=[a, b]$ and $m=(a+b) / 2$. Assuming that $I \subseteq I_{0}$ for some bounded $I_{0}$, we have $\frac{\mid\left[f^{(n+1)}(I) \mid\right.}{(n+1)!}=O(1)$. Therefore, (2) implies that $\square R_{g}(I)$ has convergence order $n+1$, and so does the range function in (1).

### 1.1 Why we must extend the CL framework

Unfortunately, there is an issue with the CL framework. To get arbitrary convergence order $n \geq 1$, we must compute the exact range $g(I)$ for a polynomial $g$ of degree $n-1$. But the endpoints of $g(I)$ might be extrema of $g$, which are generally irrational algebraic numbers when $n \geq 4$. Hence, we cannot compute the "exact range $g(I)$ " in any standard implementation models. Standard implementation models include (i) the IEEE arithmetic used in the majority of implementations, (ii) the Standard Model of Numerical Analysis [8, 17], or (iii) bigNumber packages such as GMP [7], MPFR [6], and MPFI [14]. In practice, "real numbers" are represented by dyadic numbers, that is, rational numbers of the form $m 2^{n}$ where $m, n \in \mathbb{Z}$. So, rational numbers like $1 / 3$ cannot be represented exactly. Even if we allow arbitrary rational numbers, irrational numbers like $\sqrt{2}$ are not exact. See, for example, [20] for an extended discussion of exact computation. In computer algebra systems, the largest set of real numbers which can be computed exactly are the algebraic numbers, but we do not include them under "standard implementation models" because of inherent performance issues.

In [9], we (consciously) used the term "exact computation of $g(I)$ " in a sense which is commonly understood by interval and numerical analysts, including Cornelius and Lohner. But first let us address the non-interval case: the "exact computation of $g(x)$ ". The common understanding amounts to:
$g(x)$ can be computed exactly if $g(x)$ has a closed-form
expression $E(x)$ over a set $\Omega$ of primitive operations.

There is no universal consensus on the set $\Omega$, but typically all real constants, four rational operations $( \pm, \times, \div)$, and $\sqrt{ } \cdot$ are included. For example, Neumaier $[11$, p. 6] allows these additional operations in $\Omega$ :

$$
|\cdot|, s q r, \exp , \ln , \sin , \cos , \arctan ,
$$

where ${ }^{2}$ sqr denotes squaring. Next, how does the understanding (3) extend to the exact computation of $g(I)$ ? Cornelius and Lohner stated a sufficient condition that is well-known in interval analysis [3, Theorem 1]:
$g(I)$ can be computed exactly if there is an expression $E(x)$
for $g(x)$ in which the variable $x$ occurs at most once.

It is implicitly assumed in (4) that, given an expression $E(x)$ for $g(x)$, we can compute $g(I)$ by evaluating the interval expression $E(I)$, assuming all the primitive operators in $E(x)$ have exact interval forms. But this theorem has very limited application, and cannot even compute the exact range of a quadratic polynomial $g(x)=a x^{2}+b x+c$ with $a b \neq 0$.
Example 2. To overcome the limitations of (4) in the case of a quadratic polynomial $g(x)=a x^{2}+b x+c$, we can proceed as follows: first compute $x^{*}=-b / 2 a$, the root of $g^{\prime}(x)=2 a x+b$. If $I=[\underline{x}, \bar{x}]$ ), then

$$
g(I)=[\min (S), \max (S)],
$$

where

$$
S:= \begin{cases}\{g(\underline{x}), g(\bar{x})\}, & \text { if } x^{*} \notin I \\ \left\{g\left(x^{*}\right), g(\underline{x}), g(\bar{x})\right\}, & \text { otherwise } .\end{cases}
$$

We call this the "endpoints algorithm", since we directly compute the endpoints of $g(I)$. The details when $g$ is a cubic polynomial are derived and implemented in our previous paper [9, Appendix]. How far can we extend this idea? Under the common understanding (3), we need two other ingredients:

[^1](E1) The function $g(x)$ must be exactly computable.
(E2) The roots of $g^{\prime}(x)$ must be exactly computable.
Note that (E1) is relatively easy to fulfill. For instance, $g(x)$ can be any polynomial. However, (E2) limits $g$ to polynomials of degree at most 5 , since the roots of $g^{\prime}$ are guaranteed to have closed form expressions when $g^{\prime}$ has degree at most 4 . Cornelius and Lohner appear to have this endpoint algorithm in mind when they stated in [3, p. 340, Remark 2] that their framework may reach up to order 6 convergence, namely one more than the degree of $g$.

### 1.2 Overview

In Section 2, we present our generalized CL framework for achieving range functions with any order of convergence. In Section 3, we provide details for a new family of recursive range operators ${ }^{3}\left\{\square_{4, \ell}^{H}: \ell=0,1, \ldots\right\}$ with quartic convergence order and recursion level $\ell \geq 0$, based on Hermite interpolation. In Section 4, we present our "holistic" framework for evaluating the complexity of range functions. The idea is to amortize the cost over an entire computation tree. Experimental results are in Section 5. They show that in the context of the Eval algorithm, $\square_{4}^{H}$ is superior to our previous favourite $\square_{3}^{L^{\prime}}$. The theoretical model of Section 4 is also confirmed by these experiments. Another set of experiments explore the possible speed improvements by non-maximal convergence levels. We conclude in Section 6.

### 1.3 Terminology and notation

This section reviews and fixes some terminology. Let $f: \mathbb{R}^{n} \rightarrow \mathbb{R}$ be an $n$-variate real-valued function for some $n \geq 0$. The arity of $f$ is $n$. We identify 0 -arity functions with real constants. In this paper, we do not assume that real functions are total functions. If $f$ is undefined at $\boldsymbol{x} \in \mathbb{R}^{n}$, we write $f(\boldsymbol{x}) \uparrow$; otherwise $f(\boldsymbol{x}) \downarrow$. If any component of $\boldsymbol{x}$ is undefined, we also have $f(\boldsymbol{x}) \uparrow$. Define the proper domain of $f$ as $\operatorname{dom}(f):=\left\{\boldsymbol{x} \in \mathbb{R}^{m}: f(\boldsymbol{x}) \downarrow\right\}$. If $S \subseteq \mathbb{R}^{m}$, then $f(S) \uparrow$ if $f$ is undefined at some $\boldsymbol{x} \in S$; otherwise $f(S):=\{f(\boldsymbol{x}): \boldsymbol{x} \in S\}$. Define the magnitude of $S \subseteq \mathbb{R}$ as $|S|:=\max \{|x|: x \in S\}$. Note that we use bold font like $\boldsymbol{x}$ to indicate vector variables.

The set of compact boxes in $\mathbb{R}^{n}$ is denoted $\square \mathbb{R}^{n}$; if $n=1$, we simply write $\square \mathbb{R}$. The Hausdorff distance on boxes $B, B^{\prime} \in \square \mathbb{R}^{n}$ is denoted $d_{H}\left(B, B^{\prime}\right)$. For $n=1$, it is often denoted $q(I, J)$ in the interval literature. A box form of $f$ is any function $F: \square \mathbb{R}^{n} \rightarrow \square \mathbb{R}$ satisfying two properties: (1) conservative: $f(B) \subseteq F(B)$ for all $B \in \square \mathbb{R}^{n}$; (2) convergent: for any sequence $\left(B_{i}\right)_{i=0}^{\infty}$ of boxes converging to a point, $\lim _{i \rightarrow \infty} F\left(B_{i}\right)=f\left(\lim _{i \rightarrow \infty} B_{i}\right)$. In general, we indicate box forms by a prefix meta-symbol " $\square$ ". Thus, instead of $F$, we write " $\square f$ " for any box form of $f$. We annotate $\square$ with subscripts and/or superscripts to indicate specific box forms. For example, $\square_{i} f$ or $\square^{L} f$ or $\square_{i}^{L} f$ are all box forms of $f$. In this paper, we mostly focus on $n=1$. A subdivision tree is a finite tree $T$ whose nodes are intervals satisfying this property: if interval $[a, b]$ is a non-leaf node of $T$, then it has two children represented by the intervals [ $a, m$ ] and $[m, b]$. If $I_{0}$ is the root of $T$, we call the set $\mathcal{D}=\mathcal{D}(T)$ of leaves of $T$ a subdivision of $I_{0}$.

Let $\boldsymbol{u}=\left(u_{0}, \ldots, u_{m}\right)$ denote a sequence of $m+1$ distinct points, where the $u_{i}$ 's are called nodes. Let $\boldsymbol{\mu}=\left(\mu_{0}, \ldots, \mu_{m}\right)$, where each $\mu_{i} \geq 1$ is called a multiplicity. The Hermite interpolant of $f$ at $\boldsymbol{u}, \boldsymbol{\mu}$ is a polynomial $h_{f}(x)=h_{f}(x ; \boldsymbol{u}, \boldsymbol{\mu})$ such that $h_{f}^{(j)}\left(u_{i}\right)=f^{(j)}\left(u_{i}\right)$ for all $i=0, \ldots, m$ and $j=0, \ldots, \mu_{i}-1$. The interpolant $h_{f}(x)$ is unique and has degree less than $d=\sum_{i=0}^{m} \mu_{i}$. If $m=0$, then $h_{f}(x)$ is the Taylor interpolant; if $\mu_{i}=1$ for all $i$, then $h_{f}(x)$ is the Lagrange interpolant.

## 2 Generalized CL framework

In this section, we develop an approach to computing range functions of arbitrary convergence order. To avoid the exact range computation, we replace $g(I)$ in (1) by a range function $\square g(I)$ for $g$ :

$$
\begin{equation*}
\square f(I):=\square g(I)+\square R_{g}(I) . \tag{5}
\end{equation*}
$$

We now generalize Theorem A as follows.
Theorem B. With $\square f(I)$ defined as in (5), we have

$$
d_{H}(f(I), \square f(I)) \leq d_{H}(g(I), \square g(I))+w\left(\square R_{g}(I)\right) .
$$

[^2]Proof. Consider the endpoints of the intervals $f(I), g(I)$, and $\square R_{g}(I)$ as given by

$$
f(I)=[f(\underline{x}), f(\bar{x})], \quad g(I)=[g(\underline{y}), g(\bar{y})], \quad \square R_{g}(I)=[a, b]
$$

for some $\underline{x}, \bar{x}, \underline{y}, \bar{y} \in I$ and $a, b$. We can also write

$$
\square g(I)=[g(\underline{y}), g(\bar{y})]+[\underline{\varepsilon}, \bar{\varepsilon}]
$$

for some $\underline{\varepsilon} \leq 0 \leq \bar{\varepsilon}$. Thus we have

$$
\begin{align*}
d_{H}(g(I), \square g(I)) & =\max \{-\underline{\varepsilon}, \bar{\varepsilon}\},  \tag{6}\\
\square f(I) & =[g(\underline{y}), g(\bar{y})]+[\underline{\varepsilon}, \bar{\varepsilon}]+[a, b] .
\end{align*}
$$

We write the inclusion $f(I) \subseteq \square f(I)$ in terms of endpoints:

$$
[f(\underline{x}), f(\bar{x})] \subseteq[g(\underline{y}), g(\bar{y})]+[\underline{\varepsilon}, \bar{\varepsilon}]+[a, b] .
$$

Hence,

$$
d_{H}(f(I), \square f(I))=\max \{f(\underline{x})-(g(\underline{y})+\underline{\varepsilon}+a),(g(\bar{y})+\bar{\varepsilon}+b)-f(\bar{x})\} .
$$

Since $w\left(\square R_{g}(I)\right)=b-a$ and in view of (6), our theorem follows from

$$
\begin{align*}
& f(\underline{x})-(g(\underline{y})+\underline{\varepsilon}+a) \leq-\underline{\varepsilon}+(b-a),  \tag{7}\\
& (g(\bar{y})+\bar{\varepsilon}+b)-f(\bar{x}) \leq \bar{\varepsilon}+(b-a) . \tag{8}
\end{align*}
$$

To show (7), we have, since $f(\underline{x}) \leq f(\underline{y})$,

$$
\begin{aligned}
f(\underline{x})-(g(\underline{y})+\underline{\varepsilon}+a) & \leq f(\underline{y})-(g(\underline{y})+\underline{\varepsilon}+a) \\
& =\left(g(\underline{y})+R_{g}(\underline{y})\right)-(g(\underline{y})+\underline{\varepsilon}+a) \\
& =R_{g}(\underline{y})-\underline{\varepsilon}-a \\
& \leq-\underline{\varepsilon}+(b-a) .
\end{aligned}
$$

The proof for (8) is similar.

### 2.1 Achieving any order of convergence

To apply Theorem B, we introduce precision-bounded range functions for $g(x)$, denoted $\square g(I ; \varepsilon)$, where $\varepsilon>0$ is an extra "precision" parameter. The output interval is an outer $\varepsilon$-approximation in the sense that $g(I) \subseteq \square g(I ; \varepsilon)$ and

$$
d_{H}(g(I), \square g(I ; \varepsilon)) \leq \varepsilon .
$$

We also call $\square g(I ; \varepsilon)$ a strong box function, since it implies box forms in the original sense: for example, a box form of $g$ may be constructed as

$$
\begin{equation*}
\square g(I):=\square g(I, w(I)) . \tag{9}
\end{equation*}
$$

The box form in (9) has the pleasing property that $w(I)$ is an implicit precision parameter.
Returning to the CL Framework, suppose that $f=g+R_{g}$, where $g$ has a strong range function $\square g(I ; \varepsilon)$. We now define the following box form of $f$ :

$$
\begin{equation*}
\square_{\mathrm{pb}} f(I):=\square g(I ; \varepsilon)+\square R_{\mathrm{g}}(I), \tag{10}
\end{equation*}
$$

where $\varepsilon=\left|\square R_{g}(I)\right|$. The subscript in $\square_{\mathrm{pb}}$ refers to "precision-bound". To compute $\square_{\mathrm{pb}} f(I)$, we first compute $J_{R} \leftarrow \square R_{g}(I)$, then compute $J_{g} \leftarrow \square g\left(I,\left|J_{R}\right|\right)$, and finally return $J_{g}+J_{R}$.
Corollary 1. The box form $\square_{\mathrm{pb}} f(I)$ of (10) has the same convergence order as $\square R_{g}(I)$.
For any $n \geq 1$, if $g(x)$ is a Hermite interpolant of $f$ of degree $n$, then $\square R_{g}(I)$ has convergence order $n+1$ (cf. Example 1). We have thus achieved arbitrary convergence order.
Remark 1. Theorem B is also needed to justify the usual implementations of "exact $g(I)$ " under the hypothesis (3) of the CL framework. Given an expression $E(x)$ for $g(x)$, it suffices to evaluate it with error at most $\left|\square R_{g}(I)\right|$. This can be automatically accomplished in the Core Library using the technique of "precision-driven evaluation" [21, §2].

### 2.2 Strong box functions

Corollary 1 shows that the "exact computation of $g(I)$ " hypothesis of the CL framework can be replaced by strong box functions of $g$. We now address the construction of such functions. We proceed in three stages:
A. Lipschitz expressions. Our starting point is the theory of evaluations of expressions over a class $\Omega$ of Lipschitz functions, following [11]. Let $\Omega$ denote a set of continuous real functions that includes $\mathbb{R}$ as constant functions as well as the rational operations. Elements of $\Omega$ are called primitive functions. Let $\operatorname{Expr}(\Omega)$ denote the set of expressions over $\Omega \cup X$ where $X=\left\{X_{1}, X_{2}, \ldots\right\}$ is a countable set of variables. An expression $E \in \operatorname{Expr}(\Omega)$ is an ordered DAG (directed acyclic graph) whose nodes with outdegree $m \geq 0$ are labelled by $m$-ary functions of $\Omega$, with variables in $X$ viewed as 0 -ary. For simplicity, assume $E$ has a unique root (in-degree 0 ). Any node of $E$ induces a subexpression. If $E$ involves only the variables in $\boldsymbol{X}=\left(X_{1}, \ldots, X_{n}\right)$, we may write $E(\boldsymbol{X})$ for $E$. We can evaluate $E$ at $\boldsymbol{a} \in \mathbb{R}^{n}$ by substituting $\boldsymbol{X} \leftarrow \boldsymbol{a}$ and evaluating the functions at each node in a bottom-up fashion. The value at the root is $E(\boldsymbol{a})$ and may be undefined. If $f: \mathbb{R}^{n} \rightarrow \mathbb{R}$ is a function, we call $E$ an expression for $f$ if the symmetric difference $\operatorname{dom}(E) \Delta \operatorname{dom}(f)$ is a finite set. For example, if $f(x)=\sum_{i=0}^{n-1} x^{i}$, then $E\left(X_{1}\right)=\frac{X_{1}^{n}-1}{X_{1}-1}$ is an expression for $f$, since $f(a)=E(a)$ for $a \neq 1$, but $f(1)=n$ and $E(1) \uparrow$. Similarly, we can define the interval value $E(B)$ at the box $B=\left(I_{1}, \ldots, I_{n}\right) \in \square \mathbb{R}^{n}$. If each $f$ in $E$ is replaced by a box form $\square f$, we obtain a box expression $\square E(\boldsymbol{X})$.

Following [11, pp. 33, 74], we say that $E(\boldsymbol{X})$ is Lipschitz at $B \in \square \mathbb{R}^{n}$ if the following inductive properties hold:

- (Base case) The root of $E$ is labelled by a variable $X_{i}$ or a constant function. This always holds.
- (Induction) Let $E=f\left(E_{1}, \ldots, E_{m}\right)$, where each $E_{j}$ is a subexpression of $E$. Inductively, each $E_{i}$ is Lipschitz at $B$. Moreover, $f\left(E_{1}(B), \ldots, E_{m}(B)\right)$ is defined and $f$ is Lipschitz ${ }^{4}$ in a neighbourhood $U$ of $\left(E_{1}(B), \ldots, E_{m}(B)\right) \subseteq \square \mathbb{R}^{m}$.
Theorem C [11, p. 34]. If $E(\boldsymbol{x})$ is a Lipschitz expression on $B_{0} \in \square \mathbb{R}^{n}$, then there is a vector $\ell=\left(\ell_{1}, \ldots, \ell_{n}\right)$ of positive constants such that for all $B, B^{\prime} \subseteq B_{0}$,

$$
d_{H}\left(E(B), E\left(B^{\prime}\right)\right) \leq \ell * d_{H}\left(B, B^{\prime}\right)
$$

where $d_{H}\left(B, B^{\prime}\right)=\left(d_{H}\left(I_{1}, I_{1}^{\prime}\right), \ldots, d_{H}\left(I_{n}, I_{n}^{\prime}\right)\right)$ and $*$ is the dot product.
Theorem C can be extended to the box form $\square E(\boldsymbol{X})$, and thus $\square E(B)$ is an enclosure of $E(B)$. To achieve strong box functions, we will next strengthen Theorem $C$ to compute explicit Lipschitz constants.
B. Lipschitz ${ }^{+}$expressions. For systematic development, it is best to begin with an abstract model of computation that assumes $f(B)$ and $\partial_{i} f(B)$ are computable. Eventually, we replace these by $\square f(B)$ and $\square \partial_{i} f(B)$, and finally we make them Turing computable by using dyadic approximations to reals. This follows the "AIE methodology" of [19]. Because of our limited space and scope, we focus on the abstract model.

Call $\Omega$ a Lipschitz ${ }^{+}$class if each $f \in \Omega$ is a Lipschitz ${ }^{+}$function in this sense that $f$ has continuous partial derivatives at its proper domain $\operatorname{dom}(f)$ and both $f$ and its gradient $\nabla f=\left(\partial_{1} f, \ldots, \partial_{m} f\right)$ are locally Lipschitz, that is, for all $\boldsymbol{a} \in \operatorname{dom}(f), f$ is Lipschitz on some neighbourhood $U$ of $\boldsymbol{a}$. Given an expression $E(\boldsymbol{X})$ over $\Omega$, we can define $\nabla E:=\left(\partial_{1} E, \ldots, \partial_{n} E\right)$, where each $\partial_{i} E(\boldsymbol{X})$ is an expression, defined inductively as

$$
\partial_{i} E(\boldsymbol{X})= \begin{cases}0, & \text { if } E=\text { const }  \tag{11}\\ \delta(i=j), & \text { if } E=X_{j}, \\ \sum_{j=1}^{m}\left(\partial_{j} f\right)\left(E_{1}, \ldots, E_{m}\right) \cdot \partial_{i} E_{j}, & \text { if } E=f\left(E_{1}, \ldots, E_{m}\right)\end{cases}
$$

Here, $\delta(i=j) \in\{0,1\}$ is Kronecker's delta function that is 1 if and only if $i=j$.
The above definition of $E(\boldsymbol{X})$ being "Lipschitz at $B \in \square \mathbb{R}^{n "}$ can be naturally extended to "Lipschitz ${ }^{+}$at $B$ ", that is, the inductive properties must also hold for $\left(\partial_{j} f\right)\left(E_{1}, \ldots, E_{m}\right)$ as well as $\partial_{i} E_{j}$ (cf. (11)).

[^3]```
Algorithm 1 Fine Subdivision Algorithm
Input: \(\left(f, B_{0}, \varepsilon\right.\) )
Output: An \(\varepsilon\)-fine subdivision \(\mathcal{D}\) of \(B_{0}\).
    Let \(\mathcal{D}, Q\) be queues of boxes, initialized as \(\mathcal{D} \leftarrow \varnothing\) and \(Q \leftarrow\left\{B_{0}\right\}\).
    while \(Q \neq \varnothing\) do
        \(B \leftarrow Q \cdot \operatorname{pop}()\)
        \(\left(J_{1}, \ldots, J_{n}\right) \leftarrow \nabla f(B)\)
        \(\Delta(f, B) \leftarrow \sum_{i=1}^{n}\left|J_{i}\right| \cdot w_{i}(B)\)
        if \(\Delta(f, B) \leq \varepsilon / 4\) then
            D.push( \(B\) )
        else
            \(i^{*} \leftarrow \operatorname{argmax}_{i=1, \ldots, n}\left|J_{i}\right| \cdot w_{i}(B)\)
            \(Q . \operatorname{push}\left(\operatorname{bisect}\left(B, i^{*}\right)\right) \quad \triangleright\) bisect dimension \(i^{*}\)
    Output \(\mathcal{D}\)
```

C. Strong box evaluation. Let $f: \mathbb{R}^{n} \rightarrow \mathbb{R}$ be a Lipschitz ${ }^{+}$function. Suppose it has a strong approximation function $\tilde{f}$, that is,

$$
\begin{equation*}
\tilde{f}: \mathbb{R}^{n} \times \mathbb{R}_{>0} \rightarrow \mathbb{R} \tag{12}
\end{equation*}
$$

such that $|\tilde{f}(\boldsymbol{a} ; \boldsymbol{\varepsilon})-f(\boldsymbol{a})| \leq \varepsilon$. We show that $f$ has a strong box function. Define $\Delta(f, B):=\frac{1}{2} \sum_{i=1}^{n}\left|\partial_{i} f(B)\right| \cdot$ $w_{i}(B)$. Then, for all $\boldsymbol{a} \in B$, we have

$$
|f(\boldsymbol{a})-f(\boldsymbol{m}(B))| \leq \Delta(f, B)
$$

by the mean value theorem, where $\boldsymbol{m}(B)$ is the midpoint of $B$.
Lemma 1. Let

$$
\begin{equation*}
J=J(B, \varepsilon):=\left[\tilde{f}(\boldsymbol{m}(B) ; \varepsilon / 4) \pm \frac{1}{2} \varepsilon\right], \tag{13}
\end{equation*}
$$

where $[m \pm \varepsilon]$ denotes the interval $[m-\varepsilon, m+\varepsilon]$. If $\Delta(f, B) \leq \varepsilon / 4$, then $f(B) \subseteq J$ and $d_{H}(J, f(B))<\varepsilon$.
Motivated by Lemma 1, we say that a subdivision $\mathcal{D}$ of $B_{0}$ is $\varepsilon$-fine if $\Delta(f, B) \leq \varepsilon / 4$ for each $B \in \mathcal{D}$. Given an $\varepsilon$-fine subdivision $\mathcal{D}$ of $B_{0}$, let $J(\mathcal{D}):=\bigcup_{B \in \mathcal{D}} J(B)$, where $J(B)$ is defined in (13).
Corollary 2. If $\mathcal{D}$ is an $\varepsilon$-fine subdivision of $B_{0}$, then $f\left(B_{0}\right) \subseteq J(\mathcal{D})$ and $d_{H}\left(f\left(B_{0}\right), J(\mathcal{D})\right)<\varepsilon$.
Algorithm 1 shows how to compute an $\varepsilon$-fine subdivision of any given $B_{0}$. Note that the value of $\Delta(f, B)$ is reduced by a factor less than or equal to $\left(1-\frac{1}{2 n}\right)$ with each bisection, and therefore the subdivision depth is at most $\ln \left(\varepsilon / \Delta\left(f, B_{0}\right)\right) / \ln \left(1-\frac{1}{2 n}\right)$. This bound is probably overly pessimistic (e.g., $\left|J_{i}\right|=\left|\partial_{i} f(B)\right|$ is also shrinking with depth). We plan to do an amortized bound of this algorithm. In any case, we are now able to state the key result.

Theorem D. Let $\Omega$ be a Lipschitz ${ }^{+}$class, where each $f \in \Omega$ has a strong approximation function $\tilde{f}$ as in (12). If $E(X) \in \operatorname{Expr}(\Omega)$ is Lipschitz ${ }^{+}$at $B \in \square \mathbb{R}^{n}$, then the strong box function $E(B ; \varepsilon)$ is abstractly computable from the $\tilde{f}$ 's.

Proof (sketch). Use induction on the structure of $E(\boldsymbol{X})$. The base case is trivial. If $E(\boldsymbol{X})=f\left(E_{1}, \ldots, E_{m}\right)$, then, by induction, $\tilde{I}_{i}=E_{i}\left(B ; \varepsilon_{i}\right)$ is abstractly computable $(i=1, \ldots, m)$. Lemma 1 can be generalized to allow the evaluation of $f(\tilde{B} ; \varepsilon)$, where $\tilde{B}=\left(\tilde{I}_{1}, \ldots, \tilde{I}_{m}\right)$.

Which functions satisfy the requirements of Theorem $D$ ? The hypergeometric functions (with computable parameters) is one of the most extensive class with Turing-computable strong approximation functions; Johansson [10] describes a state-of-the-art library for such functions. In [4, 5], we focused on the real hypergeometric functions and provided a uniform strong approximation algorithm, with complexity analysis for rational input parameters. In this paper, we need strong box functions which were not treated in [5, 10]; such extensions could be achieved, because hypergeometric functions are closed under differentiation. Our Theorem D shows how this is generally achieved under Lipschitz ${ }^{+}$Expressions. A complete account of the preceding theory must replace the abstract computational model by box functions $\square f$, finally giving dyadic approximations $\tilde{\square} f$ following the AIE methodology in [19]. An implementation of this approach remains future work, and we used the standard model in our experimental results.

## 3 A practical range function of order 4

In this section, we consider a new recursive range function based on Hermite interpolation, which will surpass the performance of $\square_{3}^{L^{\prime}} f\left[9\right.$, Sec. 3.1]. Let $h_{0}$ be the Hermite interpolant of $f$ based on the values and first derivatives at the endpoints of the interval $I=[a, b]$, that is, $h_{0}$ is the unique cubic polynomial with

$$
h_{0}(a)=f(a), \quad h_{0}^{\prime}(a)=f^{\prime}(a), \quad h_{0}(b)=f(b), \quad h_{0}^{\prime}(b)=f^{\prime}(b) .
$$

With $m=(a+b) / 2$ denoting the midpoint of $I$, it is not hard to show that $h_{0}$ can be expressed in centred form as

$$
h_{0}(x)=c_{0,0}+c_{0,1}(x-m)+c_{0,2}(x-m)^{2}+c_{0,3}(x-m)^{3}
$$

with coefficients

$$
\begin{array}{ll}
c_{0,0}=\frac{f(a)+f(b)}{2}-\frac{f^{\prime}(b)-f^{\prime}(a)}{4} r, & c_{0,1}=3 \frac{f(b)-f(a)}{4 r}-\frac{f^{\prime}(a)+f^{\prime}(b)}{4}, \\
c_{0,2}=\frac{f^{\prime}(b)-f^{\prime}(a)}{4 r}, & c_{0,3}=\frac{f^{\prime}(a)+f^{\prime}(b)}{4 r^{2}}-\frac{f(b)-f(a)}{4 r^{3}},
\end{array}
$$

where $r=(b-a) / 2$ is the radius of $I$. Since the remainder $R_{h_{0}}=f-h_{0}$ can be written as

$$
R_{h_{0}}(x)=\frac{\omega(x)}{4!} f^{(4)}\left(\xi_{x}\right), \quad \omega(x)=(x-a)^{2}(x-b)^{2},
$$

for some $\xi_{x} \in I$, we can upper bound the magnitude of $R_{h_{0}}(I)$ as

$$
\left|R_{h_{0}}(I)\right| \leq \Omega\left|f^{(4)}(I)\right|, \quad \Omega=\frac{|\omega(I)|}{4!}=\frac{r^{4}}{24} .
$$

To further upper bound $\left|f^{(4)}(I)\right|$, following [9, Sec. 3], we consider the cubic Hermite interpolants $h_{j}$ of $f^{(4 j)}$ for $j=1,2, \ldots, \ell$ :

$$
h_{j}(x)=c_{j, 0}+c_{j, 1}(x-m)+c_{j, 2}(x-m)^{2}+c_{j, 3}(x-m)^{3}
$$

with coefficients

$$
\begin{array}{ll}
c_{j, 0}=\frac{f^{(4 j)}(a)+f^{(4 j)}(b)}{2}-\frac{f^{(4 j+1)}(b)-f^{(4 j+1)}(a)}{4} r, & c_{j, 1}=3 \frac{f^{(4 j)}(b)-f^{(4 j)}(a)}{4 r}-\frac{f^{(4 j+1)}(a)+f^{(4 j+1)}(b)}{4}, \\
c_{j, 2}=\frac{f^{(4 j+1)}(b)-f^{(4 j+1)}(a)}{4 r}, & c_{j, 3}=\frac{f^{(4 j+1)}(a)+f^{(4 j+1)}(b)}{4 r^{2}}-\frac{f^{(4 j)}(b)-f^{(4 j)}(a)}{4 r^{3}} .
\end{array}
$$

Denoting the remainder by $R_{h_{j}}=f^{(4 j)}-h_{j}$ and using the same arguments as above, we have

$$
\begin{equation*}
\left|f^{(4 j)}(I)\right| \leq\left|h_{j}(I)\right|+\left|R_{h_{j}}(I)\right| \leq\left|h_{j}(I)\right|+\Omega\left|f^{(4 j+4)}(I)\right| . \tag{14}
\end{equation*}
$$

By recursively applying (14), we get

$$
\begin{align*}
\left|f^{(4)}\right| & \leq\left|h_{1}(I)\right|+\Omega\left|f^{(8)}(I)\right| \\
& \leq\left|h_{1}(I)\right|+\Omega\left(\left|h_{2}(I)\right|+\Omega\left|f^{(12)}(I)\right|\right) \leq \cdots \\
& \leq \sum_{j=1}^{\ell}\left|h_{j}(I)\right| \Omega^{j-1}+\Omega^{\ell}\left|\square f^{(4 \ell+4)}(I)\right|, \tag{15}
\end{align*}
$$

resulting in the remainder bound

$$
\left|R_{h_{0}}(I)\right| \leq S_{\ell}, \quad S_{\ell}:=\sum_{j=1}^{\ell}\left|h_{j}(I)\right| \Omega^{j}+\Omega^{\ell+1}\left|\square f^{(4 \ell+4)}(I)\right| .
$$

Overall, we get the recursive Hermite form of order 4 and recursion level $\ell \geq 0$,

$$
\square_{4, \ell}^{H} f(I)=h_{0}(I)+[-1,1] S_{\ell},
$$

which depends on the $4 \ell+4$ values

$$
\begin{equation*}
f^{(4 j)}(a), \quad f^{(4 j+1)}(a), \quad f^{(4 j)}(b), \quad f^{(4 j+1)}(b), \quad j=0, \ldots, \ell . \tag{16}
\end{equation*}
$$

If $f$ is analytic and $r$ is sufficiently small, or if $f$ is a polynomial, then $S_{\infty}$ is a convergent series, and we define $\square_{4}^{H} f(I):=\square_{4, \infty}^{H} f(I)$ as the maximal recursive Hermite form. Clearly, if $f$ is a polynomial of degree at most $d-1$, then $\square_{4}^{H} f=\square_{4, \ell}^{H} f$ for $\ell=\lceil d / 4\rceil-1$.

To avoid the rather expensive evaluation of the exact ranges $h_{j}(I), j=1, \ldots, \ell$, we can use the classical Taylor form for approximating them, resulting in the cheaper but slightly less tight range function

$$
\square_{4, \ell}^{H^{\prime}} f(I)=h_{0}(I)+[-1,1] S_{\ell}^{\prime},
$$

where

$$
S_{\ell}^{\prime}=\sum_{j=1}^{\ell}\left(\left|c_{j, 0}\right|+r\left|c_{j, 1}\right|+r^{2}\left|c_{j, 2}\right|+r^{3}\left|c_{j, 3}\right|\right) \Omega^{j}+\Omega^{\ell+1}\left|\square f^{(4 \ell+4)}(I)\right| .
$$

In case we also have to estimate the range of $f^{\prime}$, we can compute the $2 \ell+2$ additional values

$$
\begin{equation*}
f^{(4 j+2)}(a), \quad f^{(4 j+2)}(b), \quad j=0, \ldots, \ell \tag{17}
\end{equation*}
$$

and apply $\square_{4, \ell}^{H}$ to $f^{\prime}$. But we prefer to avoid (17) by re-using the data used for computing $\square_{4, \ell}^{H} f(I)$ in the following way. A result by Shadrin [15] asserts that the error between the first derivative of $f$ and the first derivative of the Lagrange polynomial $L(x)$ that interpolates $f$ at the 4 nodes $x_{0}, \ldots, x_{3} \in I$ satisfies

$$
\left|f^{\prime}(x)-L^{\prime}(x)\right| \leq \frac{\left|\omega_{L}^{\prime}(I)\right|}{4!}\left|f^{(4)}(I)\right|, \quad x \in I
$$

for $\omega_{L}(x)=\prod_{i=0}^{3}\left(x-x_{i}\right)$. As noted by Waldron [18, Addendum], this bound is continuous in the $x_{i}$, and so we can consider the limit as $x_{0}$ and $x_{1}$ approach $a$ and $x_{2}$ and $x_{3}$ approach $b$ to get the corresponding bound for the error between $f^{\prime}$ and the first derivative of the Hermite interpolant $h_{0}$,

$$
\left|f^{\prime}(x)-h_{0}^{\prime}(x)\right| \leq \frac{\left|\omega^{\prime}(I)\right|}{4!}\left|f^{(4)}(I)\right|, \quad x \in I
$$

Since a straightforward calculation gives $\omega^{\prime}(I)=\frac{8}{9} \sqrt{3} r^{3}[-1,1]$, we conclude by (15) that

$$
\left|R_{h_{0}}^{\prime}(I)\right| \leq \frac{8 \sqrt{3}}{9} \frac{r^{3}}{4!}\left|f^{(4)}(I)\right| \leq \frac{8 \sqrt{3}}{9} \frac{r^{3}}{4!} \frac{S_{\ell}}{\Omega}=\frac{8 \sqrt{3}}{9 r} S_{\ell},
$$

resulting in the recursive Hermite forms

$$
\square_{3, \ell}^{H} f^{\prime}(I)=h_{0}^{\prime}(I)+\frac{8 \sqrt{3}}{9 r}[-1,1] S_{\ell} \quad \text { and } \quad \square_{3, \ell}^{H^{\prime}} f^{\prime}(I)=h_{0}^{\prime}(I)+\frac{8 \sqrt{3}}{9 r}[-1,1] S_{\ell}^{\prime},
$$

which have only cubic convergence, but depend on the same data as $\square_{4, \ell}^{H} f(I)$ and $\square_{4, \ell}^{H^{\prime}} f(I)$.

## 4 Holistic complexity analysis of range functions

By the "holistic complexity analysis" of $\square f(I)$, we mean to analyse its cost over a subdivision tree, not just its cost at a single isolated interval. The cost for a node of the subdivision tree might be shared with its ancestors, descendants, or siblings, leading to cheaper cost per node. Although we have the Eval algorithm [9, Sec. 1.2] in mind, there are many applications where the algorithms produce similar subdivision trees, even in higher dimensions.

### 4.1 Amortized complexity of $\square_{3}^{L^{\prime}} f$

We first focus on the range function denoted $\square_{3}^{L^{\prime}} f$ in [9, Sec. 3.1]. This was our "function of choice" among the 8 range functions studied in [9, Table 1]. Empirically, we saw that $\square_{3}^{L^{\prime}}$ has at least a factor of 3 speedup over $\square_{2}^{T}$. Note that $\square_{2}^{T}$ was the state-of-the-art range function before our recursive forms; see the last column of the

Tables 3 and 4 in [9]. We now show theoretically that the speedup is also 3 if we only consider evaluation complexity. The data actually suggest an asymptotic speedup of at least 3.5 -this may be explained by the fact that $\square_{3}^{L^{\prime}}$ has order 3 convergence compared to order 2 for $\square_{2}^{T}$. We now seek a theoretical account of the observed speedup ${ }^{5}$.

In the following, let $d \geq 2$. Given any $f$ and interval $[a, b]$, our general goal is to construct a range function $\square f([a, b])$ based on $d$ derivatives of $f$ at points in $[a, b]$. In the case of $\square_{3}^{L^{\prime}} f([a, b])$, we need these evaluations of $f$ and its higher derivatives:

$$
f^{(3 j)}(a), \quad f^{(3 j)}(m), \quad f^{(3 j)}(b), \quad j=0, \ldots,[d / 3]-1,
$$

where $m=(a+b) / 2$. That is a total of $3[d / 3]$ derivative values. For simplicity, assume $d$ is divisible by 3 . Then the cost for computing $\square_{3}^{L^{\prime}} f([a, b])$ is $3[d / 3]=d$. Note that the cost to compute $\square_{2}^{T} f(I)$, the maximal Taylor form of order 2, is also $d$. So there is no difference between these two costs over isolated intervals. But in a "holistic context", we see a distinct advantage of $\square_{3}^{L^{\prime}}$ over $\square_{2}^{T}$ : the evaluation of $\square_{3}^{L^{\prime}} f(I)$ can reuse the derivative values already computed at the parent or sibling of $I$; no similar reuse is available to $\square_{2}^{T}$.

Given a subdivision tree $T$, our goal is to bound the $\operatorname{cost} C_{3}^{L}(T)$ of $\square_{3}^{L^{\prime}} f$ on $T$, that is, the total number of derivative values needed to compute $\square_{3}^{L^{\prime}} f(I)$ for all $I \in T$. We will write $C_{3}^{L}(n)$ instead of $C_{3}^{L}(T)$ when $T$ has $n$ leaves. This is because it is $n$ rather than the actual ${ }^{6}$ shape of $T$ that is determinative for the complexity. We have the following recurrence

$$
C_{3}^{L}(n)= \begin{cases}d, & \text { if } n=1,  \tag{18}\\ C_{3}^{L}\left(n_{L}\right)+C_{3}^{L}\left(n_{R}\right)-\frac{d}{3}, & \text { if } n \geq 2,\end{cases}
$$

where the left and right subtrees of the root have $n_{L}$ and $n_{R}$ leaves, respectively. Thus $n=n_{L}+n_{R}$. Let the intervals $I, I_{L}, I_{R}$ denote the root and its left and right children. The formula for $n \geq 2$ in (18) comes from summing three costs: (1) the cost $d$ at the root $I$; (2) the cost $C_{3}^{L}\left(n_{L}\right)$ but subtracting $2 d / 3$ for derivatives shared with $I$; (3) the cost $C_{3}^{L}\left(n_{R}\right)-2 d / 3$ attributed to the right subtree.
Theorem 1. (Amortized complexity of $\square_{3}^{L^{\prime}}$ ) The cost of computing $\square_{3}^{L^{\prime}} f(I)$ is

$$
\begin{equation*}
C_{3}^{L}(n)=(2 n+1) \cdot \frac{d}{3} . \tag{19}
\end{equation*}
$$

Thus, the cost per node is $\sim d / 3$ asymptotically.
Proof. The solution (19) is easily shown by induction using the recurrence (18). To obtain the cost per node, we recall that a full binary tree with $n$ leaves has $2 n-1$ nodes. So the average cost per node is $\frac{2 n+1}{2 n-1} \cdot \frac{d}{3} \sim d / 3$.

This factor of 3 improvement over $\square_{2}^{T}$ is close to our empirical data in [9, Sec. 5].

### 4.2 Amortized complexity of $\square_{4}^{H} f$

We do a similar holistic complexity analysis for the recursive range function $\square_{4, \ell}^{H} f(I)$ from Section 3 for any given $f$ and $\ell \geq 0$. According to (16), our recursive scheme requires the evaluation of $4(\ell+1)$ derivatives of $f$ at the two endpoints of $I$. Let $d=4(\ell+1)$, so that computing $\square_{4, \ell}^{H} f(I)$ costs $d$ derivative evaluations. For holistic analysis, let $C_{4}^{H}(n)$ denote the cost of computing $\square_{4, \ell}^{H} f(I)$ on a subdivision tree with $n$ leaves. We then have the recurrence

$$
C_{4}^{H}(n)= \begin{cases}d, & \text { if } n=1  \tag{20}\\ C_{4}^{H}\left(n_{L}\right)+C_{4}^{H}\left(n_{R}\right)-\frac{d}{2}, & \text { if } n \geq 2\end{cases}
$$

where $n_{L}+n_{R}=n$. The justification of (20) is similar to (18), with the slight difference that the midpoint of an interval $J$ is not evaluated and hence not shared with the children of $J$.

[^4]Theorem 2. (Amortized complexity of $\square_{4}^{H}$ ) The cost of computing $\square_{4, \ell}^{H} f(I)$ is

$$
\begin{equation*}
C_{4}^{H}(n)=(n+1) \cdot \frac{d}{2} . \tag{21}
\end{equation*}
$$

Thus, the cost per node is $\sim d / 4$ asymptotically.
Proof. The solution (21) follows from (20) by induction on $n$. Since a full binary tree with $n$ leaves has $2 n-1$ nodes, the average cost per node is $\frac{n+1}{2 n-1} \cdot \frac{d}{2} \sim d / 4$.
Therefore, we expect a 4 -fold speedup of $\square_{4, \ell}^{H}$ when compared to the state-of-art $\square_{2}^{T}$, and a $4 / 3$-fold or $33 \%$ speedup when compared to $\square_{3}^{L^{\prime}}$. This agrees with our empirical data below.

### 4.3 Amortized complexity for Hermite schemes

We now generalize the analysis above. Recall from Section 1.3 that $h_{f}(x)=h_{f}(x ; \boldsymbol{u}, \boldsymbol{\mu})$ is the Hermite interpolant of $f$ with node sequence $\boldsymbol{u}=\left(u_{0}, \ldots, u_{m}\right)$ and multiplicity $\boldsymbol{\mu}=\left(\mu_{0}, \ldots, \mu_{m}\right)$. We fix the function $f: \mathbb{R} \rightarrow \mathbb{R}$. Assume $m \geq 1$ and the nodes are equally spaced over the interval $I=\left[u_{0}, u_{m}\right]$, and all $\mu_{i}$ are equal to $h \geq 1$. Then we can simply write $h(x ; I)$ for the interpolant on interval $I$. Note that $h(x ; I)$ has degree less than $d:=(m+1) h$.

Our cost model for computing $\square f(I)$ is the number of evaluations of derivatives of $f$ at the nodes of $I$. Based on our recursive scheme, this cost is exactly $d=(m+1) h$ since $I$ has $m+1$ nodes. To amortize this cost over the entire subdivision tree $T$, define $N_{m}(T)$ to be the number of distinct nodes among all the intervals of $T$. In other words, if intervals $I$ and $J$ share a node $u$, then we do not double count $u$. This can happen only if $I$ and $J$ have an ancestor-descendant relationship or are siblings. Let $T_{n}$ denote a tree with $n$ leaves. It turns out that $N_{m}\left(T_{n}\right)$ is a function of $n$, independent of the shape of $T_{n}$. So we simply write $N_{m}(n)$ for $N_{m}\left(T_{n}\right)$. Therefore ${ }^{7}$ the cost of evaluating the tree $T_{n}$ is

$$
C_{d}^{h}(n):=h \cdot N_{m}(n), \quad \text { where } d=(m+1) h .
$$

Since $T_{n}$ has $2 n-1$ intervals, we define the amortized cost of a recursive Hermite range function as

$$
\bar{C}_{d}^{h}=\lim _{n \rightarrow \infty} \frac{C_{d}^{h}(n)}{2 n-1} .
$$

Theorem 3. For a recursive Hermite range function, the number of distinct nodes, the evaluation cost of $T_{n}$, and the amortized cost satisfy

$$
\begin{aligned}
N_{m}(n) & =m n+1, \\
C_{d}^{h}(n) & =h(m n+1), \\
\bar{C}_{d}^{h} & =\frac{1}{2} h m=\frac{1}{2}(d-h) .
\end{aligned}
$$

Proof. We claim that $N_{m}(n)$ satisfies the recurrence

$$
N_{m}(n)= \begin{cases}m+1, & \text { if } n=1  \tag{22}\\ N_{m}\left(n_{L}\right)+N_{m}\left(n_{R}\right)-1, & \text { if } 1<n=n_{L}+n_{R}\end{cases}
$$

The base case is clear, so consider the inductive case: the left and right subtrees of $T_{n}$ are $T_{n_{L}}$ and $T_{n_{R}}$, where $n=n_{L}+n_{R}$. Then nodes at the root of $T_{n}$ are already in the nodes at the roots of $T_{n_{L}}$ and $T_{n_{R}}$. Moreover, the roots of $T_{n_{L}}$ and $T_{n_{R}}$ share exactly one node. This justifies (22). The solution $N_{m}(n)=m n+1$ is immediate. The amortized cost is $\lim _{n \rightarrow \infty} C_{d}^{h}(n) /(2 n-1)$, since the tree $T_{n}$ has $2 n-1$ intervals.
Remark 2. Observe that the amortized complexity $\bar{C}_{d}^{h}=\frac{d-h}{2}$ is strictly less than $d$, the non-amortized cost. For any given $d$, we want $h$ as large as possible, but $h$ is constrained to divide $d$. Hence for $d=4$, we choose $h=2$. We can also generalize to allow multiplicities $\boldsymbol{\mu}$ to vary over nodes: e.g., for $d=5, \boldsymbol{\mu}=(2,1,2)$.
Remark 3. The analysis of $C_{3}^{L}(n)$ and $C_{4}^{H}(n)$ appears to depend on whether $m$ is odd or even. Surprisingly, we avoided such considerations in the above proof.

[^5]Table 1: Size of the Eval subdivision tree. Here, Eval is searching for roots in $I_{0}=\left[-r\left(I_{0}\right), r\left(I_{0}\right)\right]$.

## 5 Experimental results

To provide a holistic application for evaluating range functions, we use Eval, a simple root isolation algorithm. Despite its simplicity, Eval produces near-optimal subdivision trees [ 1,16 ] when we use $\square_{2}^{T} f$ for real functions with simple roots; see [9, Secs. 1.2, 1.3] for its description and history. We now implemented a version of Eval in $C++$ for range functions that may use any recursion level (unlike [9], which focused on maximal levels). We measured the size of the Eval subdivision tree as well as the average running time of Eval with floating point and rational arithmetic on various classes of polynomials. These polynomials have varying root structures: dense with all roots real (Chebyshev $T_{n}$, Hermite $H_{n}$, and Wilkinson's $W_{n}$ ), dense with only 2 real roots (Mignotte cluster $M_{2 k+1}$ ), and sparse without real roots $\left(S_{n}\right)$. Depending on the family of polynomials, we provide different centred intervals $I_{0}=\left[-r\left(I_{0}\right), r\left(I_{0}\right)\right]$ for Eval to search in, but always such that all real roots are contained in $I_{0}$. Our experimental platform is a Windows 10 laptop with a 1.8 GHz Intel Core i7-8550U processor and 16 GB of RAM. We use two kinds of computer arithmetic in our testing: 1024-bit floating point arithmetic and multi-precision rational arithmetic. In rational arithmetic, $\sqrt{3}$ is replaced by the slightly larger $17320508075688773 \times 10^{-16}$. Our implementation, including data and Makefile experiments, may be downloaded from the Core Library webpage [2].

We tested eleven versions of Eval that differ by the range functions used for approximating the ranges of $f$ and $f^{\prime}$; see Tables $1-3$. Generally, $\mathrm{E}_{k, \ell}^{X}\left(X=T, L^{\prime}, H, H^{\prime}\right.$ for Taylor, cheap Lagrange, Hermite, cheap Hermite forms) refers to using Eval with the corresponding forms of order $k$ and level $\ell$ ( $\ell$ may be omitted when the level is maximal). The first three, $\mathrm{E}_{2}^{T}, \mathrm{E}_{3}^{L^{\prime}}, \mathrm{E}_{4}^{L^{\prime}}$, are the state-of-the-art performers from [9], followed by three non-maximal variants of $\mathrm{E}_{3}^{L^{\prime}}$, namely $\mathrm{E}_{3, \ell}^{L^{\prime}}$ for $\ell \in\{10,15,20\}$. The next two, $\mathrm{E}_{4}^{H}$ and $\mathrm{E}_{4}^{H^{\prime}}$, are based on the maximal recursive Hermite forms $\square_{4}^{H} f$ and $\square_{3}^{H} f^{\prime}$ and their cheaper variants $\square_{4}^{H^{\prime}} f$ and $\square_{3}^{H^{\prime}} f^{\prime}$, respectively, and the last three derive from the non-maximal variants of the latter, again for recursion levels $\ell \in\{10,15,20\}$.

Table 1 reports the sizes of the Eval subdivision trees, which serve as a measure of the tightness of the underlying range functions. In each row, the smallest tree size is underlined. As expected, the methods based on range functions with quartic convergence order outperform the others, and in general the tree size decreases as the recursion level increases, except for sparse polynomials. It requires future research to investigate the latter. We further observe that the differences between the tree sizes for $\mathrm{E}_{4}^{L^{\prime}}$ and $\mathrm{E}_{4}^{H^{\prime}}$ are small, indicating that the tightness of a range function is determined mainly by the convergence order, but much less by the type of local interpolant (Lagrange or Hermite). However, as already pointed out in [9, Sec. 5], a smaller tree size does not necessarily correspond to a faster running time. In fact, $\mathrm{E}_{3}^{L^{\prime}}$ was found to usually be almost as fast as $\mathrm{E}_{4}^{L^{\prime}}$, even though the subdivision trees of $\mathrm{E}_{3}^{L^{\prime}}$ are consistently bigger than those of $\mathrm{E}_{4}^{L^{\prime}}$.

In Tables 2 and 3 we report the running times for our eleven Eval versions and the different families of polynomials. Times are given in seconds and averaged over at least four runs (and many more for small

Table 2: Average running time of Eval with 1024-bit floating point arithmetic in seconds.

degree polynomials). The last three columns in both tables report the speedup ratios $\sigma(\cdot)$ of $\mathrm{E}_{4}^{H^{\prime}}, \mathrm{E}_{4,15}^{H^{\prime}}$, and $\mathrm{E}_{3,15}^{L^{\prime}}$ with respect to $\mathrm{E}_{3}^{L^{\prime}}$, which was identified as the overall winner in [9].

In Figure 1, we provide a direct comparison of the Eval version based on our new range function $\mathrm{E}_{4}^{H^{\prime}}$ with the previous leader $\mathrm{E}_{3}^{L^{\prime}}$ : for the test polynomials in our suite, the new function is faster for polynomials of degree greater than 25 , with the speedup approaching and even exceeding the theoretical value of 1.33 of Section 4.2. In terms of tree size they are similar (differing by less than $5 \%$, Table 1). Hence, $\mathrm{E}_{4}^{H^{\prime}}$ emerges as the new winner among the practical range functions from our collection.

### 5.1 Non-maximal recursion levels

High order of convergence is important for applications such as numerical differential equations. But a sole focus on convergence order may be misleading as noted in [9]: for any convergence order $k \geq 1$, a subsidiary measure may be critical in practice. For Taylor forms, this is the refinement level $n \geq k$ and for our recursive

Figure 1: Speedup $\sigma$ of $\mathrm{E}_{4}^{H^{\prime}}$ with respect to $\mathrm{E}_{3}^{L^{\prime}}$ for different families of polynomials and varying degree: raw (left) and smoothed with moving average over five points (right).

Figure 2: Speedup $\sigma(\ell)$ of $\mathrm{E}_{3, \ell}^{L^{\prime}}$ (left) and $\mathrm{E}_{4, \ell}^{H^{\prime}}$ (right) against their maximal level counterparts with respect to $\ell$ for polynomials of degree 125 (top) and 250 (bottom) from different families.
range functions, it is the recursion level $\ell \geq 0$. Note that Ratschek [12] has a notion called "order $n \geq 1$ " for box forms on rational functions that superficially resembles our level concept. When restricted to polynomials, it diverges from our notion. In other words, we propose to use ${ }^{8}$ the pair ( $k, \ell$ ) of convergence measures in evaluating our range functions. In [9] we focused on maximal levels (for polynomials) after showing that

[^6]the $\tilde{\square}_{2}^{T}$ (the minimal level Taylor form of order 2) is practically worthless for the EvaL algorithm. We now experimentally explore the use of non-maximal levels.

Figure 2 plots the (potential) level speedup factor $\sigma(\ell)$ against level $\ell \geq 0$. More precisely, consider the time for Eval to isolate the roots of a polynomial $f$ in some interval $I_{0}$. Let $\square_{k, \ell} f$ be a family of range functions of order $k$, but varying levels $\ell \geq 0$. If $E_{k, \ell}$ (resp., $E_{k}$ ) is the running time of Eval using $\square_{k, \ell} f$ (resp., $\square_{k, \infty} f$ ), then $\sigma(\ell):=E_{k} / E_{k, \ell}$. Of course, it is only a true speedup if $\sigma(\ell)>1$. These plots support our intuition in [9] that minimal levels are rarely useful (except at low degrees). Most strikingly, the graph of $\sigma(\ell)$ shows a characteristic shape of rapidly increasing to a unique maxima and then slowly tapering to 1 , especially for polynomials $f$ with high degrees. This suggests that for each polynomial, there is an optimal level to achieve the greatest speedup. In our tests (see Figure 2), we saw that both the optimal level and the value of the corresponding greatest speedup factor depend on $f$. Moreover, we observed that the achievable speedup tends to be bigger for $\mathrm{E}_{4}^{H^{\prime}}$ than for $\mathrm{E}_{3}^{L^{\prime}}$ and that it increases with the degree of the polynomial $f$.

## 6 Conclusions and future work

We generalized the CL framework in order to achieve, for the first time, range functions of arbitrarily high order of convergence. Our recursive scheme for such constructions is not only of theoretical interest, but are practical as shown by our implementations. Devising specific "best of a given order" functions like $\square_{4, \ell}^{H} f(I)$ is also useful for applications.

The amortized complexity model of this paper can be used to analyse many subdivision algorithms in higher dimensions. Moreover, new forms of range primitives may suggest themselves when viewed from the amortization perspective.

We pose as a theoretical challenge to explain the observed phenomenon of the "unimodal" behaviour of the $\sigma(\ell)$ plots of Figure 2 and to seek techniques for estimating the optimal recursion level that achieves the minimum time. Moreover, we would like to better understand why the size of the Eval subdivision tree increases with $\ell$ in the case of sparse polynomials (see Table 1), while it decreases for all other polynomials from our test suite.

Finally, we emphasize that strong box functions have many applications. Another future work therefore is to develop the theory of strong box functions, turning the abstract model of Section 2.2 into an effective (Turing) model in the sense of [19].

[^0]:    ${ }^{1}$ Definitions of our terminology are collected in Section 1.3.

[^1]:    ${ }^{2}$ The appearance of $s q r$ may be curious, but that is because he will later define interval forms of the operations in $\Omega$.

[^2]:    ${ }^{3}$ Each $\square_{4, \ell}^{H}$ is an operator that transforms any sufficiently smooth function $f: \mathbb{R} \rightarrow \mathbb{R}$ into the range function $\square_{4, \ell}^{H} f$ for $f$.

[^3]:    ${ }^{4}$ The concept of a function $f$ (not expression) being Lipschitz on a set $U$ is standard: it means that there exists a vector $\ell=$ $\left(\ell_{1}, \ldots, \ell_{m}\right)$ of positive constants, such that for all $\boldsymbol{x}, \boldsymbol{y} \in U \subseteq \mathbb{R}^{m},|f(\boldsymbol{x})-f(\boldsymbol{y})| \leq \boldsymbol{\ell} *|\boldsymbol{x}-\boldsymbol{y}|$ where $*$ is the dot product and $|\boldsymbol{x}-\boldsymbol{y}|=$ $\left(\left|x_{1}-y_{1}\right|, \ldots,\left|x_{m}-y_{m}\right|\right)$. Call $\boldsymbol{\ell}$ a Lipschitz constant vector for $U$.

[^4]:    ${ }^{5}$ Note that in our EvaL application, we must simultaneously evaluate $\square_{3}^{L^{\prime}} f(I)$ as well as its derivative $\square_{2}^{L^{\prime}} f^{\prime}(I)$. But it turns out that we can bound the range of $f^{\prime}$ for no additional evaluation cost.
    ${ }^{6}$ If $d$ is not divisible by 3 , we can ensure a total cost of $d$ evaluations per interval of the tree but the tree shape will dictate how to distribute these evaluations on the $m+1$ nodes.

[^5]:    ${ }^{7}$ The notation " $C_{d}^{h}(n)$ " does not fully reproduce the previous notations of $C_{3}^{L}(n)$ and $C_{4}^{H}(n)$ (which were chosen to be consistent with $\square_{3}^{L^{\prime}}$ and $\square_{4}^{H}$ ). Also, $d$ is implicit in the previous notations.

[^6]:    ${ }^{8}$ This is a notational shift from our previous paper, where we indexed the recursion level by $n \geq 1$. Thus, level $\ell$ in this paper corresponds to $n-1$ in the old notation.
